## *Fasting Insulin Levels and Weight Gain*

### Typical Reference Ranges

Optimal (metabolically healthy): 2–6  $\mu\text{IU}/\text{mL}$  (or  $\text{mIU}/\text{L}$ , same units)

Borderline elevated: 7–9  $\mu\text{IU}/\text{mL}$  — often indicates early insulin resistance, even if glucose is still normal.

Elevated / concerning:  $\geq 10$   $\mu\text{IU}/\text{mL}$  — typically considered hyperinsulinemia and associated with increased risk of fat storage, difficulty losing weight, and eventual glucose dysregulation.

### Why It Matters

Even mild elevations in fasting insulin reflect that your body needs to secrete more insulin to maintain normal glucose levels. Chronically high insulin levels:

- Promote fat storage, especially in the abdomen
- Inhibit lipolysis (fat breakdown)
- Increase hunger and cravings via leptin and ghrelin signaling
- Often precede measurable changes in fasting glucose or HbA1c

### Ideal Targets

For weight control and metabolic health, aim for:

- Fasting insulin  $< 5$   $\mu\text{IU}/\text{mL}$ , ideally closer to 3 if achievable without hypoglycemia
- HOMA-IR (fasting glucose  $\times$  insulin / 405)  $< 1.0$  indicates strong insulin sensitivity
